Abstract: *Colletogloeopsis zuluensis*, previously known as *Coniothyrium zuluense*, causes a serious stem canker disease on *Eucalyptus* spp. grown as non-natives in many tropical and sub-tropical countries. This stem canker disease was first reported from South Africa and it has subsequently been found on various species and hybrids of *Eucalyptus* in other African countries as well as in countries of South America and South-East Asia. In previous studies, phylogenetic analyses based on DNA sequence data of the ITS region suggested that all material of *C. zuluensis* was monophyletic. However, the occurrence of the fungus in a greater number of countries, and analyses of DNA sequences with additional isolates has challenged the notion that a single species is involved with Coniothyrium canker. The aim of this study was to consider the phylogenetic relationships amongst *C. zuluensis* isolates from all available locations and to support these analyses with phenotypic and morphological comparisons. Individual and combined phylogenies were constructed using DNA sequences from the ITS region, exons 3 through 6 of the β-tubulin gene, the intron of the translation elongation factor 1-α gene, and a partial sequence of the mitochondrial ATPase 6 gene. Both phylogenetic data and morphological characteristics showed clearly that isolates of *C. zuluensis* represent at least two taxa. One of these is *C. zuluensis* as it was originally described from South Africa, and we provide an epitype for it. The second species occurs in Argentina and Uruguay, and is newly described as *C. gauchensis*. Both fungi are serious pathogens resulting in identical symptoms. Recognising them as different species has important quarantine consequences.

**Key words:** Bayesian inference, *Colletogloeopsis*, *Eucalyptus* canker, multilocus gene phylogeny, Mycosphaerella.

**Taxonomic novelty:** *Colletogloeopsis gauchensis* M.-N. Cortinas, Crous & M.J. Wingf. sp. nov.

**INTRODUCTION**

*Colletogloeopsis zuluensis* (M.J. Wingf., Crous & T.A. Cout.) M.-N. Cortinas, M.J. Wingf. & Crous (Cortinas et al. 2006) causes a serious stem canker disease on *Eucalyptus* species. The disease was first reported in 1987 in South Africa, and the pathogen was described as a species of *Coniothyrium*, namely *C. zuluense* M.J. Wingf., Crous & T.A. Cout. (Wingfield et al. 1997). The disease spread very rapidly through the country, initially occurring only on a single *Eucalyptus grandis* clone, but ultimately occurring in all parts of South Africa with a sub-tropical climate, and on a wide variety of *Eucalyptus* species and hybrids. Substantial research has thus been undertaken to better understand the disease and to develop disease-resistant planting stock through breeding and selection programmes (Van Zyl et al. 1997, 2002a).

Symptoms of Colletogloeopsis canker are very obvious, at least at the onset of disease. Initial infections include small, circular necrotic lesions on the green stem tissue in the upper parts of trees. These lesions expand, becoming elliptical, and the dead bark covering them typically cracks, giving a “cat-eye” appearance (Fig. 1). Lesions coalesce to form large cankers that girdle the stems, giving rise to the production of epicormic shoots and ultimately trees with malformed or dead tops. Infections occur annually on the new green tissue and they penetrate the cambium to form black kino-filled pockets. Thus kino pockets with irregular borders of infected tissue can be seen within the infected wood of trees coincident with the annual rings (Fig. 1). Small black pycnidia can be seen on the surface of dead bark tissue (Fig. 1), from where black conidial tendrils exude under moist conditions. Conidia are small, aseptate and dematiaceous, appearing black in colour when seen in mass on the host or agar media.

Subsequent to the discovery of Coniothyrium canker in South Africa, the disease has been found in many other countries. Its first discovery outside South Africa was in Thailand where it is associated with typical symptoms on *E. camaldulensis* (Van Zyl et al. 2002b). More recently, the disease has been found in other countries in Africa (Alemu et al. 2003, 2005), South and Central America (Roux et al. 2002, Alemu et al. 2004), as well as South-East Asia (Old et al. 2003, Cortinas et al. 2004, 2006) (Fig. 2). Interestingly, the disease remains unknown in the areas of origin of *Eucalyptus*, although it might occur there at very low and undetectable levels (Wingfield 2003, Slippers et al. 2005).

The first taxonomic treatment of *C. zuluensis* was based on morphological characteristics of the pathogen. The presence of pycnidia and pigmented aseptate, ellipsoid conidia arising from percurrently proliferating conidiogenous cells were consistent with species placed in *Coniothyrium* Corda. DNA sequence comparisions have, however, made it possible to recognise that the fungus has a clear phylogenetic position in *Mycosphaerella* Johanson (Alemu et al. 2005). It is moreover not related to species of *Coniothyrium* s. str., which are anamorphs of
Fig. 1. External symptoms of the stem canker disease on *E. grandis* in Uruguay caused by *C. gauchensis*. A, B. Mature clones showing the typical lesions on the surface of the trunk. C. Distinctive black circular lesions on green twigs. D. Stem with typical cracked lesions. E. Stem showing internal symptoms below the bark lesions. F. Kino-pockets of infected tissue within the wood. G. Pycnidia on cracked lesions.
Leptosphaeria spp. This realisation has led to the transfer of Coniothyrium zuluense to Colletogloeopsis Crous & M.J. Wingf. (Cortinas et al. 2006). Colletogloeopsis is a well-recognised Mycosphaerella anamorph and its circumscription was amended to include species with pycnidial conidiomata. Within Mycosphaerella, C. zuluensis clusters with a group of well-known leaf and stem pathogens of Eucalyptus including M. ambiphylla A. Maxwell, M. cryptica (Cooke) Hansf., M. molleriana (Thûm.) Lindau, M. nubilosa (Cooke) Hansf., M. vespa Carnegie & Keane, M. suttonii Crous & M.J. Wingf., and Phaeosphleospora eucalypti (Cooke & Massee) Crous, F.A. Ferreira & B. Sutton (Cortinas et al. 2006).

Different isolates of C. zuluensis have been found to be highly variable in morphology (Fig. 3) and pathogenicity to different Eucalyptus clones (Van Zyl 1997, Wingfield et al. 1997, Van Zyl 2002a). Nonetheless, previous phylogenetic analyses based on the nuclear ribosomal small subunit (18S) and internal transcribed spacer regions and the ribosomal 5.8 gene (ITS1, 5.8S, ITS2) had shown that C. zuluensis was monophyletic (Van Zyl 2002b, Alemu et al. 2005). As additional surveys of Eucalyptus plantations are undertaken, an understanding of the geographical range of C. zuluensis continues to expand. Additional isolates from new regions have thus become available for DNA sequence comparisons and these have provided the opportunity to re-examine the taxonomic status of C. zuluensis, and the variation observed in its morphology and pathogenicity.

The aim of this study was to consider whether the previously recognised C. zuluensis can be retained when applying multi-gene analyses using a large collection of isolates not previously available. To accomplish this objective, individual and combined phylogenetic analyses using the ITS region, β-tubulin gene (BT2), the elongation factor 1-α (EF1-α) gene, and the mitochondrial ATPase 6 (ATP6) gene, were carried out. Morphological and other phenotypic characters were also considered.

MATERIALS AND METHODS

Isolates
A collection of 45 isolates was chosen to reflect the geographical distribution of C. zuluensis. In addition, several species of Mycosphaerella known to be closely related to C. zuluensis were also included (Table 1). All these isolates were obtained from the culture collection (CMW) of the Forestry and Agricultural Biotechnology Institute (FABI), Pretoria, South Africa. Single-conidial cultures were established from mature pycnidia isolated from lesions taken from the stems of Eucalyptus trees in South Africa and Uruguay. The contents of single pycnidia were diluted in sterile distilled water, and spread on the surface of Petri dishes containing MEA (20 g/L Biolab malt extract, 15 g/L Biolab agar). After 24–36 h, germinating conidia were transferred to fresh MEA plates and incubated for 30 d at 25 ºC. Reference strains are preserved in CMW, and have been deposited at the Centraalbureau voor Schimmelcultures (CBS), Utrecht, The Netherlands (Table 1). Nomenclature, descriptions and illustrations were deposited in MycoBank.

DNA extraction and amplification
To extract DNA, mycelium was scraped from the surface of cultures grown in Petri dishes, freeze dried, frozen in liquid nitrogen and ground to a fine powder. The protocol followed by Cortinas et al. (2004) was simplified as follows: DBE extraction buffer (200 mM Tris-HCl pH 8, 150 mM NaCl, 25 mM EDTA pH 8, 0.5 % SDS) was added directly to the ground mycelium and incubated for 2 h at 80 ºC (or until pigments changed colour from green to red). In the extraction-DNA enrichment procedure, one volume of phenol was used first and one volume of a 1:1 phenol-chloroform solution thereafter.

Four gene regions were amplified for all isolates included in this study (Fig. 4). The ITS region of the ribosomal DNA was targeted using the primers ITS1: 5’TCC GTA GGT GAA CCT GCC G and ITS4: 5’GCT GCG TTC TTC ATC GAT GC (White et al. 1990). Exons 3 to 6 and the respective introns (BT2) of the β-tubulin gene region were amplified using the primers BT2A: 5’GGT AAC CAA ATC GGT GCT TTC and BT2B: 5‘AAC CTC ATG GTA GTG ACC CTT GGC (Glass & Donaldson 1995). The intron sequence of the EF1-α gene was amplified using the primers EF1-728F: 5’CAT CGA GAA CTA CCT GGG C and EF1-986R: 5’TAC TGG TTA AAG GAA CCC TTA CC (Carbon & Kohn 1999) and intron 2 and exon 3 of the ATP6 gene was amplified using the set of primers 5’ATT AAT TSW CCW TTA GAW CAA TT and 5’TAA TTC TAN WGC ATC TTT AAT RTA developed by Kretzer & Bruns (1999).

PCR reactions were prepared in a total volume of 25 µL including 1.5 µL of genomic 1/10 dilution DNA, 1 U of Taq polymerase, 10 × Taq buffer, 10 pmol of each primer, 0.8 mM of each dNTPs, and 2.0 mM MgCl₂ (ITS) or 4.0 mM MgCl₂ (BT2, EF1-α, ATP6). PCR amplicons were visualised under UV light on 1 % or 2 % agarose gels. Different cycling conditions were used for the various gene regions. For the ITS region, 96 ºC, 3 min initial denaturation and cycles of 95 ºC, 30 s, 54 ºC, 30 s, 72 ºC, 1 min were repeated 10 times followed by 25 cycles of 95 ºC, 30 s, 56 ºC, 30 s, 72 ºC, 1 min with 5 s extension after two cycles. A final elongation step of 7 min at 72 ºC was also included. The same cycling conditions were used for ATP6 region changing the annealing temperature to 50 ºC.

CMW= Culture collection of the Forestry and Agricultural Biotechnology Institute (FABI), University of Pretoria, South Africa.  
CBS= Culture collection of the Centraalbureau voor Schimmelcultures, Uppsalalaan, Utrecht, The Netherlands.  
CPC= Culture collection of Pedro Crous housed at CBS.
For β-tubulin, 96 °C, 3 min initial denaturation and cycles of 95 °C, 30 s, 57 °C, 45 s, 72 °C, 45 s were repeated 40 times. For EF1-α, 96 °C, 3 min and cycles of 95 °C, 30 s, 54 °C, 45 s, 72 °C, 45 s were repeated 40 times with 5 s extension after two cycles. A final elongation step of 7 min at 72 °C was included.

PCR amplification products were purified using Sephadex G-50 columns (Sigma- Aldrich, Steinheim, Germany) or treated with a mix of Exonuclease III and Shrimp alkaline phosphatase (Exo-Sap); 0.7 U of each enzyme per PCR reaction were incubated at 37 °C for 15 min followed by 80 °C for 15 min before sequencing. Sequencing reactions were prepared in 10 µL with 2 µL of purified PCR product, 10 pmol of the same primers used for the first PCR amplifications, 2 µL 5× dilution buffer and ABI Prism Big Dye Terminator mix, v. 3.1 (Applied Biosystems Inc., Foster City, California).

Sequencing PCR cycles consisted of 25 repetitions at 96 °C, 10 s; 50 °C, 4 s; 60 °C, 4 min. Sequencing reactions were cleaned using Sephadex G-50 or precipitated using EDTA, Sodium Acetate and Ethanol according to the protocol supplied by Applied Biosystems (Applied Biosystems Inc., Foster City, California).

Phylogenetic analyses
Alignments of sequence data were made using Clustal W under MEGA 3.0 (Kumar et al. 2004) and manually adjusted. All sequences generated in this study were deposited in GenBank (Table 1). Alignments were deposited in TreeBASE.

Maximum parsimony and distance analyses were conducted considering the individual and combined partitions. Most parsimonious (MP) trees were generated using PAUP v. 4.0b10 (Swofford 2002).

Fig. 3. Characteristics of isolates of Group 1 (C. zuluensis), and isolates of Group 2 (C. gauchensis). Columns A–C show three different colony morphologies belonging to the Group 2 isolates: CMW 7272, CMW 7269, CMW 7293. Columns D–F show three different colony morphologies that belong to the Group 1 isolates: CMW 7488, CMW 5236, CMW 7479.

Fig. 4. Schematic structural organization of the genomic regions used in this study. ITS regions and intron sequences are represented in solid black. Letters “I” indicate introns and letters “E” indicate exons. Sizes of the individual and combined partition alignments are given in brackets. Note that intron between E3 and E4 in the BT2 region is not present.
Table 2. Summary of the shared fixed positions found in the DNA regions of ITS, BT2, EF1-α and ATP6 among Colletogloeopsis isolates associated with Eucalyptus stem cankers. The total number of fixed shared positions between the two groups is given in the last column.

*Location of the fixed shared polymorphisms. The number in this cell and in all the other cells represent the location of fixed shared polymorphisms. They are defined in base pairs counting from the beginning of the alignment.

bThe first letter before the slash bar represents the state character shared by isolates of the group 1, C. zuluensis.

°Character state shared by isolates of the group 2, C. gauchensis.

The grey box in the EF1-α line indicates the position of the 20 bp in/del that could be used for diagnostic purposes.

For parsimony analyses, heuristic searches were used with the steepest descent option and the TBR swapping algorithm. The characters were equally weighted and treated as unordered. Statistical support of the nodes in the trees was tested with 1000 bootstrap replicates. Distance analyses were conducted using MEGA 3.0 (Kumar et al. 2004). Pairwise distances were estimated using the Kimura with two parameters model (Kimura 1980). A gamma distribution $\alpha = 0.5$ was used to take into account the differences in mutation rate among sites, due to the mix of coding and non-coding sequences present in the analysed fragments. The individual gene reconstructions were performed with Minimum Evolution (Rzhetsky & Nei 1993). Gaps generated in the alignment were treated as missing data. One thousand bootstrap replicates were made to assess the statistical support of the nodes in the phylogenetic trees. Trees were rooted to midpoint.

Partitions were considered together using Bayesian analyses (Ronquist & Huelsenbeck 2003). It has recently been shown that the Bayesian method is more sensitive to under-specification than over-specification of the evolutionary model (Huelsenbeck & Rannala 2004) when calculating the posterior probabilities. Consequently, a time-reversible complex model with gamma-distributed rate variation ($GTR + I + G$) was selected to combine the data sets. This model of DNA substitution allows the consideration of different rates of substitutions among sites, different nucleotide frequencies, and differences in the rate of substitutions among nucleotides. Therefore, four sets of analyses were run in MrBayes 3.1.1 (Huelsenbeck & Ronquist 2001, Ronquist & Huelsenbeck 2003) calculating marginal posterior probabilities using the selected time reversal $GTR + I + G$ model of nucleotide substitution (Tavaré 1986, Yang 1993, 1994) and default values for the prior settings. Four Monte Carlo Markov chains were run for 3 million generations. Trees and parameters were recorded every 100 generations. Likelihood stability was reached at 30 000 generations. This number of generations was then established as the "burn-in" period (represented by 3001 trees). A half compatible consensus tree was recovered from the remaining sampled trees. The Bayesian procedure was repeated four times. The posterior probabilities are indicated close to the respective nodes on the tree and the sequences of Mycosphaerella colombiensis Crous & M.J. Wingf. and M. suttonii Crous & M.J. Wingf. were used as outgroups.

Temperature sensitivity studies

Plugs (3 mm diam) of colonised agar were cut from actively growing cultures and placed at the centres of Petri dishes containing MEA. Isolates tested for growth characteristics at different temperatures included those from South Africa (CMW 7442, CMW 7449, CMW 7479, CMW 7488), and others from Uruguay (CMW 7269, CMW 7274, CMW 7279, CMW 7300). Three plates were prepared for each isolate and these were incubated at temperatures between 5 °C and 35 °C at 5 °C intervals, for 6 wk. A second set of isolates from Ethiopia (CMW 8282, CMW 8292) and from China (CMW 15966, CMW 15971) were tested in a similar manner but for an incubation period of 8 wk. Growth was recorded weekly by measuring average colony diameter.
Fig. 5. Partial alignment of isolates showing the characteristic 20 bp elongation factor 1-α in/del. The presence of the in/del identifies the Group 1 isolates (light grey) from Group 2 (dark grey) isolates. All isolates in Table 1 can be assigned correctly into Groups 1 or 2 according to the presence/absence of this fragment.

Fig. 6. Phylograms generated using Minimum Evolution and K2P with gamma distribution, nr 1. A. ITS. B. β-1 tubulin. C. EF1-α. D. ATP6. Values on branches are bootstrap support (1000 replicates).
Morphology
Descriptions are based on sporulation *in vivo*. Wherever possible, 30 measurements (× 1000 magnification) were made of structures mounted in lactic acid, the 95% deviation determined, and the extremes of spore measurements given in parentheses. Colony colours (surface and reverse) were assessed after 25 d on MEA at 25 °C in the dark, using the colour charts of Rayner (1970).

RESULTS

PCR and sequence analyses
Sequenced amplicons obtained from *C. zuluensis* isolates for the four different gene regions were aligned to study fixed polymorphisms. Alignments of 469 bp (ITS), 308 bp (BT2), 254 bp (EF1-α) and 656 bp (ATP6) were generated. The intron between the exons 3 and 4 of the β-tubulin gene was missing in all isolates studied. Visual analyses of the characters defined two groups among the isolates based on the fixed, shared polymorphisms. The first group included isolates from South Africa, China, Thailand, Vietnam and Malawi and a second group comprised isolates from Uruguay, Argentina, Hawaii, Uganda and Ethiopia. Positions in base pairs of the different fixed characters in the alignments for the various isolates are shown in Table 2. Five fixed characters were found at the ITS region, eleven were found in the BT2 dataset, eight were found at the EF1-α intron where a 20-base-pair indel was also found (Fig. 5). One fixed position was found in the ATP6 region.

Phylogenetic analyses
Individual phylograms were obtained for each gene region and parsimony data produced very similar

---

**Fig. 7.** Bayesian combined tree using a GTR+G+I model of substitutions. Posterior probabilities are shown on the branches. Parsimony bootstrap values are shown in brackets.
topologies to those of the distance trees. Therefore, only distance trees are presented (Fig. 6). In all cases the Bootstrap cut-off of 70% was established.

Analyses of sequence data for the ITS region resolved two coherent clusters for the Colletogloeopsis isolates considered. These groups represented isolates from South Africa, Malawi, Mexico, Thailand, Vietnam and China (Group 1) and those from Uruguay, Argentina, Hawaii, Ethiopia and Uganda (Group 2). The separation of these two groups had 98 % bootstrap support in the ITS tree. In the BT2 and EF-1α trees, these two groups had 99 % and 100 % support, respectively. For the ATP6 tree, three groups could be distinguished although only one of these had strong support (100 %). The group having reasonable support included isolates from Vietnam, Mexico, Malawi, China and South Africa. Internal sub-clusters could be distinguished within the Group 1 and Group 2 clusters in the ITS, BT2 and EF1-α trees. These sub-clusters had greater than 70 % bootstrap support only in the BT2 tree. The assortment of isolates within the sub-clusters was different in different trees.

The level of polymorphism observed in the datasets was different for each individual analysed region. The β-tubulin data set presented the highest level of variation followed by the EF1-α, ITS and ATP6 data sets, respectively. A close inspection of the ATP6 data matrix showed few polymorphisms explaining the poor resolution obtained in the tree.

After the individual analyses, combined parsimony and Bayesian analysis were carried out (Fig. 7). The reconstructed trees included the collection of Colletogloeopsis isolates together with Mycosphaerella spp. A posterior probability of 1 and 100 % bootstrap value separated the Colletogloeopsis isolates from the rest of Mycosphaerella spp. The parsimony and Bayesian half-compatible trees showed two major groups representing isolates from South Africa, Malawi, Mexico, Thailand, Vietnam and China (Group 1) and those from Uruguay, Argentina, Hawaii, Ethiopia and Uganda (Group 2) supported by posterior probabilities of 1 and 0.95 and 98 % and 100 % bootstrap values, respectively. A rich internal topology was found within these two groups. Numerous sub-clusters were supported with high probabilities and bootstrap values. A number of these included more than one isolate from the same locality. Nevertheless, location was not sufficient to explain how the sub-clusters were formed.

Temperature sensitivity studies
Average colony diameter for the isolates from South Africa and from Uruguay was different at some of the tested temperatures after 6 wk (Fig. 8). No measurable growth was found at 5 °C, optimal growth occurred between 20 and 25 °C, and the diameters of colonies decreased when they were incubated at temperatures of 30 °C and above. Differences between isolates from the two regions were seen at 10 °C where the Uruguayan isolates grew more rapidly than isolates from South Africa. Between 20 °C and 25 °C both groups of isolates achieved their maximum diameter. Nevertheless, these maximum diameters were smaller for the Uruguayan isolates. The most obvious difference between South African and Uruguayan isolates was

![Fig. 8. Results of culture growth studies at different temperatures. A. Isolates from South Africa and Uruguay were tested for a period of 6 weeks and those from China and Ethiopia for a period of 8 weeks. Each point on the graph represents the average of 6 measurements taken at each temperature.](image-url)
observed at 35 °C. At this temperature, the Uruguayan isolates hardly displayed growth whereas South African isolates reached between 10 and 20 mm diam.

The results obtained in a second experiment including isolates from China and Ethiopia, were very similar to those comparing isolates from South Africa and Uruguay. After 8 wk, the differences in growth of the isolates from both origins were obvious at 35 °C (Fig. 8). This is consistent with the fact that isolates from China are phylogenetically related to those from South Africa and those from Ethiopia are related to those from Uruguay.

**Morphology**

Isolates of *Colletogloeopsis* included in this study were morphologically variable in culture. Colony characteristics overlapped for isolates from South Africa and Uruguay, but it was possible to recognise some characteristics apparently exclusive to the Uruguayan isolates. Likewise, distinctly different conidial and conidiogenous cell characteristics were found when isolates from Uruguay were compared with those of *C. zuluensis* from South Africa (Fig. 9). The range of conidial lengths overlapped almost entirely between *C. zuluensis* [conidia (4–)4.5–5(–6) × 2–2.5(–3.5) µm] and the isolates from Uruguay [conidia (4–)5–6(–7.5) × (2–)2.5(–3) µm]. The Uruguayan conidia, however, had a larger maximum length, reaching 7.5 µm (6 µm for *C. zuluensis*). Conidia of *C. zuluensis* were slightly wider (3.5 µm) as opposed to those from Uruguay, which were an average of 3 µm. Another distinctive characteristic of the fungus from Uruguay is that it has sympodial polyphialidic conidiogenous cells, which is different to *C. zuluensis*, which has percurrently proliferating monophialidic conidiogenous cells.

**Taxonomy**

Phylogenetic analyses in this study supported two distinct groups of isolates, encompassed within the fungus currently treated as *C. zuluensis*. One of these groups of isolates is from South Africa, Malawi, Thailand, Vietnam, China and Mexico. The other group includes isolates from Uruguay, Argentina, Hawaii-U.S.A., Ethiopia and Uganda. These fungi can also be separated by characteristics of growth in culture, morphology and growth at different temperatures. Clearly, the South African fungus must retain the name *C. zuluensis*. At the time of describing this fungus, no ex-type cultures were deposited. We have thus provided a suite of isolates for which DNA sequence data are available, and that are tied to herbarium specimens to serve as epitypes. The fungus occurring in Uruguay and other countries represents a distinct taxon that is described below.

**Colletogloeopsis gauchensis** M.-N. Cortinas, Crous & M.J. Wingf., sp. nov. MycoBank MB500854. Figs 9–10.
**Etymology:** Named after the gauchos people of South America that live in the same area where this species is distributed and where it was first collected. In the same genus, *C. zuluensis* is named after the KwaZulu-Natal Province and the “Zulu” people of South Africa.

*Colletogloeopsis zuluensis* similis, sed conidiosi angustioribus, (4–)5–6–(7.5) × (2–)2.5–(3) μm et phialidibus nonnumquam sympodialiter proliferentibus distincta.

Lesions caulicolous, subcircular to irregular, dark brown, 2–10 mm diam, with a raised, red-brown border. *Conidiomata* pycnidial to somewhat acervular, subepidermal, single, rarely aggregated, occurring in necrotic tissue, globose to slightly depressed, becoming erumpent, up to 120 μm diam, exuding conidia in a long cirrus; conidiomatal walls composed of 2–3 layers of medium brown textura angularis; opening by a central ostiole or irregular rupture; ostiolar region lined with thick-walled, brown, smooth, septate hyphae that are sometimes branched below, 3–4 μm wide, with obtuse ends that flare apart (upper 1–6 cells). *Conidiophores* subcylindrical, subhyaline to medium brown, smooth to finely verruculose, mono- to polyphialidic, proliferating percurrently, with several percurrent proliferations near the apex. *Conidia* medium brown, thick-walled, finely verruculose, broadly ellipsoidal, apex obtuse to subobtuse, base subtruncate to bluntly rounded, (4–)5–6–(7.5) × (2–)2.5–(3) μm; base frequently with a minute marginal frill.

**Cultural characteristics:** Colony characteristics on MEA at 25 ºC are variable. Colony colours were similar to those of *C. zuluensis* (Van Zyl et al. 1997, 2002). Surface colours range from greyish yellow-green, dull green, isabelline, greenish olivaceous to grey-olivaceous; colonies in reverse range from dark grey, dark olive-grey to dark green (Rayner 1970); margins are smooth, regular or irregular. Some cultures develop a characteristic white outer zone of aerial mycelium (Fig. 3). Paler colonies develop smoother surfaces with white aerial mycelium; some strains produce a diffuse yellow pigment in MEA.

Notes: *Colletogloeopsis gauchensis* [conidia (4–)5–6–(7.5) × (2–)2.5–(3) μm] can readily be distinguished from *C. zuluensis* [conidia (4–)4.5–5–(6) × 2–2.5–(3.5) μm] by its slightly longer conidia, and the presence of sympodial polyphialidic conidiogenous cells (Figs 9–10). Furthermore, it grows readily at 10 ºC, with hardly any to no growth at 35 ºC. In contrast, *C. zuluensis* grows more slowly at 10 ºC, and faster at 35 ºC than *C. gauchensis*, and strains of *C. gauchensis* do not form conidiomata in culture.

**DISCUSSION**

Phylogenetic analyses for a large number of *C. zuluensis* isolates from different parts of the world and based on multiple gene regions have shown clearly that this material represents at least two discrete taxa. These species are described based on material from South Africa and Uruguay, but both taxa include collections from many different countries. Thus *C. zuluensis* is now known from South Africa, Malawi, Thailand, Vietnam, China and Mexico. Likewise, *C. gauchensis* described in this study occurs not only in Uruguay but also in Argentina, Hawaii-U.S.A., Ethiopia and Uganda. The two fungi thus represent distinct phylogenetic species but they can clearly be distinguished from each other based on morphological characteristics and growth characteristics in culture.

Twenty-six fixed nucleotide positions allowed us to separate the collection of *C. zuluensis* s. lat. isolates used in this study into two distinctive groups. One of
these fixed polymorphisms found in the EF1-α intron can easily be used to discriminate between *C. zuluensis* and *C. gauchensis*. This 20 bp fragment between positions 153 to 172 in *C. zuluensis* is absent in *C. gauchensis*. The p-distance among the *Colletogloeopsis* isolates considered in this study displayed a range of 0 to 1 % divergence in ITS sequences, 0–8 % for BT2 sequences, 0–24 % for EF1-α sequences and 0–4 % for ATP6 data-matrices respectively. These ranges showed that there was sufficient variation within *Colletogloeopsis* to suspect that more than one taxon was represented in the collection of isolates. The distances are also consistent with values used in previous studies (Couch & Kohn 2002, Barnes et al. 2005) to separate taxa.

Very few morphological differences were found between isolates of *C. zuluensis* from South Africa and isolates of *C. gauchensis* from Uruguay. These differences include the fact that Uruguayan isolates have polyphialidic, sympodially and percurrently proliferating conidiogenous cells as opposed to the monophialidic, percurrently proliferating conidiogenous cells in *C. zuluensis*. The conidia of *C. gauchensis* are also consistently longer than those of *C. zuluensis* (Figs 9–10). Furthermore, *C. gauchensis* is adapted to cooler climates than *C. zuluensis*. On the contrary, isolates of *C. zuluensis* grow well at 35 °C, whereas those of *C. gauchensis* barely grow at this temperature.

Results of this study provide added support for the view that *C. zuluensis* and *C. gauchensis* are anamorphs of *Mycosphaerella*. They have an allopatric distribution and are considered sibling species only in terms of the fact that they are ecologically and morphologically very similar. The extent to which cryptic and sibling species occur in taxonomic groups varies depending on the group of fungi studied. However, the discovery of cryptic species such as *C. gauchensis* in this study is becoming a commonplace when DNA studies are implemented (see Crous et al. 2006). Results of such studies reveal that these species reflect collections of morphologically similar taxa that can only be discriminated based on minute morphological details or characteristics in pure culture. A further example of such a species complex in *Mycosphaerella* concerns “*Coniothyrium* ovatum” H.J. Swart (Crous et al. 2004a, b, 2006 – this volume), which will be treated elsewhere (Cortinas et al. in prep.).

Intraspecific variation detected amongst isolates of *C. zuluensis* and to a lesser extent *C. gauchensis* showed internal structure in the individual and combined trees. Such intraspecific structure was only well-supported in the BT2, ATP6 and combined trees. Based solely upon the phylogenetic species concept, it would be possible to recognise additional species especially in this complex. For the present, however, we choose to not provide additional names before robust population biology studies are available.

Coniothyrium canker is one of the most important diseases of *Eucalyptus* worldwide (Old et al. 2003). In South Africa, it appeared relatively suddenly in a very limited location and spread rapidly, resulting in very substantial losses to the local forestry industry. The disease has also caused substantial damage to plantations in other countries such as Argentina and Uruguay. It is thus intriguing that there are two distinct fungi associated with indistinguishable symptoms. The origin of the fungus is unknown and it is not known to occur in the native range of *Eucalyptus*. The evidence from this study shows that the two fungi are closely related and have adapted differently based on some ecological factor. Like most *Mycosphaerella* spp. they are highly host-specific to certain species of *Eucalyptus*, grow poorly in culture, and thus it seems reasonable to expect that their origin would be on *Eucalyptus* or a host closely related to it. A similar situation has emerged for species of *Chrysoporthe* Gryzenh. & M.J. Wing. (Gryzenhout et al. 2004). That are well-known pathogens of *Eucalyptus* but that appear to have originated on a wide variety of woody plants in the order *Myrtales* (Wingfield 2003, Gryzenhout et al. 2004, Seixas et al. 2004).

Recognition of two species within a collection of isolates that have previously been recognised as belonging to the single taxon has important consequences for disease control and quarantine. In the past, it has been suggested that the fungus originated in South Africa, and that it was restricted to that country (Wingfield et al. 1997). Thus, the appearance of the disease in other countries has often been linked to the movement of plant material and particularly seed to other countries. Although it has not been shown experimentally that *C. zuluensis* is moved on seed, this appears to be a likely mode of global distribution. There is a large international trade in *Eucalyptus* seed, which is variably controlled and monitored. Both *C. zuluensis* and *C. gauchensis* have now wide geographic distributions and this implies that they have been spread from one or a number of sources. Every effort should now be made to restrict them from further movement to new countries and areas.

**ACKNOWLEDGEMENTS**

We thank the FABI administrative and culture collection support staff as well as our colleagues Irene Barnes, Wolfgang Maier and Gavin Hunter for their assistance and helpful comments. We also acknowledge the National Research Foundation, members of the Tree Protection Co-operative Program (TPCP), the Centre of Excellence in Tree Health Biotechnology and the THRIP initiative of the Department of Trade and Industry, South Africa for financial support.
